

Randomized min-cut algorithm

Consider the randomized min-cut algorithm discussed in class. We have seen that its probability of success is at least $1/\binom{n}{2}$, where n is the number of its vertices.

- Describe how to implement the algorithm when the graph is represented by adjacency lists, and analyze its running time. In particular, a contraction step can be done in $O(n)$ time.
- A weighted graph has a weight $w(e)$ on each edge e , which is a positive real number. The min-cut in this case is meant to be min-weighted cut, where the sum of the weights in the cut edges is minimum. Describe how to extend the algorithm to weighted graphs, and show that the probability of success is still $\geq 1/\binom{n}{2}$. [hint: define the weighted degree of a node]
- Show that running the algorithm multiple times independently at random, and taking the minimum among the min-cuts thus produced, the probability of success can be made at least $1 - 1/n^c$ or a constant $c > 0$ (hence, with high probability).

SOLUTION

First Point

Second Point

In the algorithm we change the way we choose an edge to contract: edges with high weight will have a greater probability to be chosen with respect to others with lower weight. We define $weight : E \rightarrow \mathbb{R}$ as the function that associate the weight to a given edge. We will use the $weight$ function also on subsets of E , intending for $weight(X)$ with $X \subseteq E$ the sum of the weight of all the edges in X .

$$weight(X) = \sum_{e \in X} weight(e) \quad \text{where } X \subseteq E$$

As seen in class, the *min cut* is not unique, nevertheless the sum of weights in all *min_cuts* is the same, than with a notation abuse we will call it $weight(min_cut)$. For each edge $x \in E$ the probability to be choose for a contraction is given by its weights normalized with the total sum of the weights of all the edges of the graph.

$$Pr[extract\ x] = \frac{weight(x)}{weight(E)}$$

Now the probability of making an error, when extracting an edge at random, is the probability of extracting one of the “bad” edges, i.e. edges such that their contraction cause a variation in $weight(min_cut)$. We name *BAD* the set of “bad” edges.

$$Pr[error] = \sum_{e \in BAD} Pr[extract\ e] = \sum_{e \in BAD} \frac{weight(e)}{weight(E)} = \frac{weight(BAD)}{weight(E)} \quad (1)$$

As usual bad edges are those belonging to every *min cut*, so the total weight of bad edges is less or equal to the weight of *min cut*.

$$weight(BAD) \leq weight(min_cut) \quad (2)$$

Given a node v , we define $star(v)$ as the set of all the edges touching v . For the same reasons explained in class, for each node v the weight of *min cut* must be less or equal to the sum of the weights of the edges touching v . This is because otherwise we would have a cut, $star(v)$, with weight less than *min cut*, which is absurd.

$$\forall v \in V . weight(min_cut) \leq weight(star(v)) \quad (3)$$

We can reformulate the *handshaking lemma* for weighted graph in the following way, in which $weight(star(v))$ is something like the “weighted degree” of the node v .

$$weight(E) = \frac{\sum_{v \in V} weight(star(v))}{2} \quad (4)$$

Now we can derive:

$$weight(E) = \frac{\sum_{v \in V} weight(star(v))}{2} \quad (\text{from 4})$$

$$\geq \frac{|V|weight(min_cut)}{2} \quad (\text{from 3})$$

$$weight(min_cut) \leq \frac{2 weight(E)}{|V|} \quad (5)$$

Finally we have all the ingredients for the proof:

Theorem 1. *Selecting the edges for the contraction according to the probability described, each time we choose an edge the probability of choosing a “bad” edge is less or equal than $2/|V|$.*

$$Pr[error] \leq \frac{2}{|V|}$$

Proof.

$$Pr[error] = \frac{weight(BAD)}{weight(E)} \quad (\text{from 1})$$

$$\leq \frac{weight(min_cut)}{weight(E)} \quad (\text{from 2})$$

$$\leq \frac{\frac{2 weight(E)}{|V|}}{weight(E)} \quad (\text{from 5})$$

$$= \frac{2 weight(E)}{|V|weight(E)} = \frac{2}{|V|}$$

□

The probability of making an error when selecting an edge is the same as for the case of a normal graph seen in class, so the probability of success for the algorithm (i.e. the probability of choosing well all the times) is still $\geq 1/\binom{n}{2}$.

Third Point

We know that $P(n) \geq 1/\binom{n}{2}$ is the probability of choose well for N times. We have seen also that the probability of error is $\leq 1 - 1/\binom{n}{2}$. Then the probability of having an error each time in N repetitions of the algorithm is

$$leq(1 - \frac{1}{\binom{n}{2}})^N \approx e^{-\frac{2N}{n(n-1)}}$$

Given a c we want the probability of success to be $\geq 1 - 1/n^c$. This is equivalent to ask that the probability of error is $\leq 1/n^c$. Making some calculations:

$$\frac{1}{e^{\frac{2N}{n(n-1)}}} = e^{-\frac{2N}{n(n-1)}} \leq \frac{1}{n^c}$$

$$n^c \leq e^{\frac{2N}{n(n-1)}}$$

$$\ln(n^c) \leq \ln(e^{\frac{2N}{n(n-1)}}) = \frac{2N}{n(n-1)}$$

$$N \geq \frac{n(n-1)\ln(n^c)}{2}$$

So, for each given c , to make the probability of success at least $1 - 1/n^c$ is sufficient to take N grater or equal than $\frac{1}{2}n(n-1)\ln(n^c)$.
